# Comparing Flat File Systems and Relational Database Systems.

| <i>Feature</i>         | <i>Flat File System</i>                  | <i>Relational Database System</i>               |
|------------------------|--|---|
| <i>The Structure</i>   | Simple with text and binary files        | Uses Tables with rows and columns to store data |
| <i>Data Redundancy</i> | High risk of duplicated files            | Low since normalized data reduces duplication   |
| <i>Relations</i>       | None since they're structured in folders | Built in using foreign keys                     |
| <i>Usages</i>          | CSV Files , .log files                   | MySQL, Oracle                                   |
| <i>Disadvantages</i>   | Poor Scalability and no integrity checks | Complex Setup and requires maintenance          |

## Database Advantages : Mind Map

# Roles in a Database System

| Role                   | Responsibilities  |
|------------------------|---|
| System Analyst         | Collects requirements, determines the system scope, engages with stakeholders |
| Database Designer      | Creates ERDs and defines schema   |
| Database Developer     | Implements schema, writes SQL queries   |
| Database Administrator | Manages DB performance, backups, security, assigns user roles                 |
| Application Developer  | Integrates DB with applications, handles API/database calls                   |
| BI Developer           | Designs reports and dashboards  |
|                        |   |

# Types of Databases

## Relational vs. Non-Relational:

- Relational: Structured, SQL-based (e.g., MySQL, PostgreSQL)
- Non-Relational: Flexible schema, document/key-value (e.g., MongoDB, Cassandra)

| Type        | Description                       | Use Case                       |
|-------------|-----------------------------------|--------------------------------|
| Centralized | Single location, easier control   | Small businesses, local apps   |
| Distributed | Multiple nodes, high availability | Global apps, real-time systems |
| Cloud       | Hosted by providers, scalable     | SaaS platforms, mobile apps    |

# Cloud Storage and Database

Consider cloud storage as a distant file cabinet where you can open a lock no matter the location-where you can lodge insider so you can use it any time it is required. And since nobody wants to work with nuts and bolts, these services tidily bundle up all you need to operate a database: the database engine itself, routine backing up and even the facility to upscale or downscale element with minimal bother.

What is the point of using it? The first ones are scalability, availability and cost-efficiency. The physical location of the data in the cloud means that it can be easy to scale up or scale down the resources at any given time, and that the provider will undertake regular maintenance.

Downsides? Vendor lock-in seller lock-in, once you are a customer that is tied to a certain provider, moving can be a complicated, costly process and there is the issue of latency and data privacy.

The best-known are Azure SQL, Amazon RDS, and Google Cloud Spanner. Glip-diagram, in a moment, how a cloud DB usually arranges itself.
